A Tier 1 USDOT University Transportation Center at The University of Texas at Austin

D-STOP is a collaborative initiative by researchers at the Center for Transportation Research and the Wireless Networking and Communications Group at The University of Texas at Austin.
In this project, we refined an approach to using data collected by the City of Austin’s traffic monitoring cameras to automatically identify pedestrian activities on roadways. Our approach automatically analyzes the content of video data gathered by existing traffic cameras using a semi-automated processing pipeline powered by state-of-art computing hardware and algorithms. The method also extracts a background image at analyzed locations, which is used to visualize locations where pedestrians are present and display their trajectories. We illustrate the use of a scalable tool for the automated analysis of data collected from monocular traffic cameras that can allow agencies to leverage existing infrastructure in the analysis and mitigation of pedestrian safety concerns with two use cases.

This work focuses on the following two major goals: 1) evaluation of pedestrian activities before and after a pedestrian hybrid beacon device installation; and 2) assessment of pedestrian activities at new locations. The specific activities can be further grouped into four tasks: Task 1: Pedestrian crossing detection before and after PHB installation at Anderson location; Task 2: Recording and analysis of pedestrian crossing event at Rundberg location; Task 3: Recording and analysis of pedestrian crossing at Payton location; and, Task 4: Bus stop usage inferences at Payton location. In this report, we document our efforts, findings, challenges, and achievements in this project.

Executive Summary
In Video Analytics for Vision Zero 3, we have continued to refine an approach to use data collected by the City of Austin’s traffic monitoring cameras to automatically identify pedestrian activities on roadways. Our approach automatically analyzes the content of video data gathered by existing traffic cameras using a semi-automated processing pipeline powered by state-of-art computing hardware and algorithms. The method also extracts a background image at analyzed locations, which is used to visualize locations where pedestrians are present and display their trajectories. We illustrate the use of a scalable tool for the automated analysis of data collected from monocular traffic cameras that can allow agencies to leverage existing infrastructure in the analysis and mitigation of pedestrian safety concerns with two use cases.

Our work has been focused on the following two major goals: 1) evaluation of pedestrian activities before and after a pedestrian hybrid beacon device installation; and 2) assessment of pedestrian activities at new locations. For the first goal, we have explored additional algorithms for the pedestrian tracking code, namely SORT, and refined our pedestrian detection by further limiting regions of interest. We have evaluated the SORT algorithm at Anderson Lane and Burnet Road (hereafter “Anderson location”). For the second goal, we have evaluated two additional locations, Lamar and Rundberg (hereafter “Rundberg location”) and Lamar Boulevard and Payton Gin Road (hereafter “Payton location”). The specific activities can be further grouped into four tasks: Task 1: Pedestrian crossing detection before and after PHB installation at Anderson location; Task 2: Recording and analysis of pedestrian crossing event at Rundberg location; Task 3: Recording and analysis of pedestrian crossing at Payton location; and, Task 4: Bus stop usage inferences at Payton location. In this report, we document our efforts, findings, challenges, and achievements for the below work tasks.
1. Introduction
The rise in pedestrian fatalities in the US over the past few years has led many transportation agencies to refocus efforts on implementing proven safety countermeasures to improve pedestrian safety. As approximately 75 percent of pedestrian fatalities occur at mid-block locations, much focus is placed on strategies to facilitate safer pedestrian crossings. One such treatment, the pedestrian hybrid beacon (PHB), has been shown to reduce serious injury and fatal crashes by 15 percent and pedestrian crashes by nearly 70 percent [1]. Over the past decade the City of Austin has installed more than seventy-five PHBs at locations characterized by documented pedestrian demand, crash history, and long distances between safe crossing opportunities, among other factors. When studying potential PHB locations, the City has traditionally relied on manual observations to quantify pedestrian movements, such as the number of crossings over a given time period. However, manual observations provide information only for limited time periods, making it challenging to quantify the evolution of pedestrian behavior over time or in response to a treatment such as a PHB.

The collection and analysis of video data at critical locations provides an opportunity to analyze pedestrian movements and to provide a verifiable account of road user behavior. The former reduces the need to rely on ad hoc decision making [2]. However, if analyses are conducted by human observers, there is a limit to the number of locations and analysis periods that may be considered. Automated approaches to effectively recognize, analyze, and store pedestrian activities over time are needed. The technical challenges associated with pedestrian activity analysis using traffic monitoring video data are different from those faced when conducting traffic flow analyses. Regular roadside cameras have wide and deep fields of view. Pedestrian activities occupy only a small portion of the field, and at many locations are only present sporadically. Further, pedestrians appear smaller in size than cars and are more frequently subject to obstruction from other objects within the scene.

Incorporating Internet of Things (IoT) and smart devices within an intelligent transportation system (ITS) usually comes with substantial up-front costs for installation and deployment. At the same time, advances in algorithm development and software design bring new opportunities to increase utilization of existing transportation infrastructure. To address these challenges, we have continued developing a video processing pipeline [3] to improve pedestrian detection and tracking specifically. We have implemented additional features, including select areas of interest from the video frames, reporting additional measures of object detections, incorporating heuristics based on best practices, additional visualization summarization, and manual video curation utilities.

Beginning in Section 2, we describe the work according to task. Task 1: Pedestrian crossing detection before and after PHB installation at Anderson location; Task 2: Recording and analysis of pedestrian crossing event at Rundberg location; Task 3: Recording and analysis of pedestrian crossing at Payton location; and, Task 4: Bus stop usage inferences at Payton location. In Section 3, we describe other challenges and achievements during the past year of work. We conclude and discuss main findings in Section 4.
2. Tasks Performed

2.1 Task 1: Pedestrian crossing detection before and after PHB installation at Anderson location

At the Anderson location, analyses were conducted before and after the activation of a PHB device that facilitates safe pedestrian crossings in the area, many of which are related to an active bus stop. We have applied our approach to compare pedestrian street-crossing patterns before and after at the intersection of Anderson Lane and Burnet Road (hereafter “Anderson location”) during the previous year. The aim for this year is to explore additional algorithms in order to improve the quality of pedestrian crossing detection.

Table 1 Data collection summary for Anderson location

The time range and size of video recordings selected for computational analysis are summarized in Table 1. This task is a continuation from the prior year.

Figure 1 Percentage of different types of activities curated by students.
In addition to computational detection of pedestrian crossing events, we have asked students to manually curate and count pedestrian crossing events. The purpose of student curation is to create ground truth data for evaluation of algorithm prediction and detections. There are 44 hours videos that have been curated: September 19, 2019; September 29, 2019; February 13, 2020; and, February 23, 2020 (partially finished). For each 15-minute video, the curation takes on average 0.57 hours to finish. There are five categories of activities: walking, standing, crossing, cycling, and waiting. There is also an “other category” for all other activities. Figure 1 shows the percentage of different types of activities curated by students.

To further understand the effectiveness of our approach, we explored an alternative algorithm approach, “Single Online and Real time Tracking” (SORT) [14]. The SORT algorithm identifies tracks in three steps as follows:

- **Step 1: Track initialization.** Pedestrians are assigned tracks at the start of the video or as new pedestrians enter the frame.
- **Step 2: Track estimation:** A forecast algorithm (Kalman filter) is used to predict the location of pedestrian in future frames based on velocity (requires a “burn-in” of a few frames).
- **Step 3: Track association.** Cost optimization (Hungarian algorithm) is used to associate pedestrians into tracks across frames based on the velocity forecast and overlap of bounding boxes.

![Figure 2 Visualization of tracks identified through SORT algorithm before and after PHB installation.](image)

The basic idea of SORT algorithm is similar to our current approach for pedestrian tracking with two key differences. First, we used a customized heuristic algorithm instead of Kalman filtering for track position estimation. Second, our tracking algorithm only considers the center of the bounding box rather than the entire bounding box. Figure 2 shows a summarized view of tracks identified by SORT before and after PHB installations.
We compared the direct output of SORT algorithm and student curated results over the same videos. The results show a significant overcounting of crossing events. This is similar to the observation we have with our tracking algorithm - there are a number of short tracks among tracks identified. The short tracks are caused by group crossing and/or frames with obstruction views of pedestrians. To address this issue, we have also applied two filters: “length-based filter” and “probability-based filter.” The length-based filter is based on the length of the track and duration of the tracks. The probability-based filter will filter length based on the distribution of all predicted tracks and remove any tracks with a probability of observation less than a predefined threshold. As a result, predicted tracks can be greatly reduced due to removal of short or rarely expected tracks. Figure 4 shows the results after applying value filters.

Figure 4 Visualization of tracks identified through SORT algorithm before and after PHB installation. The tracks are filtered based on distance (>100 pixels) and duration (150 frames minimum).
We also compared filtered SORT results with student curated results. Figure 5 shows comparisons of using length-based filter and probability-based filter respectively. In both figures, the blue bar is for “Student_count_total” which is the number of people the student curators identified. The red bar shows the “Student_count_events” which is the number of distinct crossing events student curators identified. The green bar is the “SORT_count” which is the number of trajectories identified by the SORT algorithm after filters. The two filters show very similar performances. In both results, we noticed for some hours, the predicted results are very close to actual counts, such as hours 7, 14, 15, and 19. There is significant undercounting during afternoon hours, such as hours 17 and 18. There is significant overcounting during the morning hours such as hours 8 and 9.

Figure 5 Top: Comparisons of predicted crossing tracks and curated tracks. Crossing tracks are filtered by distance (>100 pixels) and duration (150 frames minimum). Bottom: Comparisons of predicted crossing tracks and curated tracks. Crossing tracks are filtered by the probability of observations.
2.2 Task 2: Recording and analysis of pedestrian crossing event at Rundberg location

We started video collection at the Rundberg location in March 2019. We have continued our video collection through November 2019. The Rundberg location analyses are focused on volume and location of pedestrian frequently crossing the street. This is an important step toward understanding the impact of measures designed to promote street crossing on designated safe areas, such as crosswalks. We have automated video captures in 15 minute intervals at each location during the period from November 07, 2019, to December 17, 2019. Since the camera angle and direction can be dynamically adjusted by staff at City of Austin for other purposes, video recordings that capture activity away from the location of interest to the case studies are discarded. There are 38 days with good recordings except 11/17/2019, 12/10/2019, and 12/15/2019. Additionally, there are several days during which we do not have full recordings, including 11/9, 11/26, 11/29, 12/12, and 12/14/2019. The rough time range and size of video recordings selected for computational analysis are summarized in Table 2.

The pedestrian activities for each day during the selected periods are summarized in Figure 6 at the Rundberg location. Each blue point shows the maximum number of pedestrians detected in any single frame in a one-minute slice of a video (where one minute is inferred from frame numbers given a 30fps framerate). The red line is a 30-minute rolling average over those maximum pedestrian counts. Pedestrians outside of the road are excluded from these counts. Figure 7 shows the combined view for each hour over all days.
Figure 6 Summary of Pedestrian activities at Rundberg Location
2.3 Task 3: Recording and analysis of pedestrian crossing at Payton location
The Payton location is another location selected for a focused study on pedestrian crossing detections. We have accumulated roughly a month-long recording from 3/7/2020 to 4/8/2020. Most recordings were deemed usable between 10am to 8pm. The raw recording is about 40~50 GB per day, with a total of ~1.4TB total recorded video.

Figure 7 Pedestrian detection per 30-minute window for all days, color-coded by weekend or week days.

Figure 8 Visual summary results at Payton location during week days (03/09~03/13 and 03/16~03/19). The activities are colored for four time periods of the day: Yellow: 7-10 am; Green: 10:00-13:00; Blue: 13:00~16:00; Red: 16:00~19:00.
Pedestrian detections are then processed to derive tracks of crossing events as illustrated in Figure 8 (week days) and Figure 9 (weekends). The activities are colored for four time periods of the day: Yellow: 7:00-10:00; Green: 10:00-13:00; Blue: 13:00~16:00; Red: 16:00~19:00. The Yellow and Red groups correspond to peak traffic hours while Blue and Green groups are for off-peak hours.

Figure 9 Visual summary results at Payton location during Weekends (03/07~03/08 and 03/14~03/15) The activities are colored for four time periods of the day: Yellow: 7:00-10:00; Green: 10:00-13:00; Blue: 13:00~16:00; Red: 16:00~19:00.

Figure 10 shows our initial crossing event prediction over all recordings (left) as well as separated by directions of travel (right). In Figure 11, average hourly detections are shown (left) as well as separated by directions of travel.

Figure 10 Daily crossing prediction summary (left) and separated by directions (right).
We suspect there is an over estimate of the number of crossing events shown in both Figure 10 and 11. To address the issue, we have developed a new strategy to identify a crossing event by only considering pedestrian detected in the median of the road. Figure 12 shows a visual summary of tracks detected in the region confined to the middle of the road.

Figure 12 Visual summary results at Payton location during week days (03/09–03/13 and 03/16–03/19). The activities are colored for four time periods of the day: Yellow: 7:00-10:00; Green: 10:00-13:00; Blue: 13:00–16:00; Red: 16:00–19:00.
Figure 13 shows the number of hourly crossing detections after only consider median of the road. The overall results are similar with previous prediction results with total hourly crossing over all days are between 10~30. In comparison, results from Figure 10 and 11 shows 20–50 percent higher detections.

2.4 Task 4: Bus stop usage at Payton location

Figure 14 Locations of two bus stops from camera view and Google map views.
There are also two bus stops visible from the camera views at the Payton location. In this task, our goal is to infer bus stop usage from the camera (i.e., how many people are waiting for buses throughout the day). Comparing to crossing event detection, there is a major difference that is the pedestrians are relatively motionless while waiting for buses. Hence, we adapt our crossing event detection algorithm from detecting tracks of movement to identifying “time blocks” of non-movement for the same pedestrian as follows:

- Step 1. Define two areas of interests and count pedestrian detection and time periods.
- Step 2. Identify all person detection in the selected area.
- Step 3. Identify non-continuous time blocks with person identification. Multiple blocks within 5 seconds are considered as one time block.
- Step 4. Identify number of persons within each time block.
- Step 5. Filter by length of time block. All time blocks whose length is less than 5 seconds are discarded.

Table 3 shows the results of a number of detections for each step of detection algorithms. The final detection results for weekend and week days are shown in Figures 16 and 15 respectively.
Figure 15 Visual summary results of waiting for bus at Payton location during week days (03/09–03/13 and 03/16–03/19) The activities are colored for four time periods of the day: Yellow: 7:00–10:00; Green: 10:00–13:00; Blue: 13:00–16:00; Red: 16:00–19:00.

Figure 16 Visual summary results of waiting for bus at Payton location during weekends (03/07–03/08 and 03/14–03/15) The activities are colored for four time periods of the day: Yellow: 7:00–10:00; Green: 10:00–13:00; Blue: 13:00–16:00; Red: 16:00–19:00.
We obtained data from Capital Metro of bus onboarding statistics in the previous year (Figure 17). Note that our detection algorithm cannot effectively distinguish onboarding and alighting. The total number of people detected and the hourly trend seems in-line with Capital Metro statistics. Our inference seems slightly higher. There are more person detections at the southbound stop (on the left). This may be because it’s closer and more visible from the camera so that additional persons (drivers, cyclists) may be more easily detected.

Figure 17 Bus stop usage statistics provided by Capital Metro.

Figure 18 Detection results on number of people waiting for bus per hour.
3. Challenges and Achievements

3.1 COVID-19 impact
Our work progress has been directly impacted by COVID-19 in the following way: Our video recording pipeline was disrupted due to a change of network access policy and heightened security requirements on both the UT side (TACC and CTR) and at the City of Austin. As a result, we were unable to record over a longer period of time since May.

We were planning to finish the student curation on all videos at the Anderson location. However, due to school closures, the Vislab is no longer accessible to students. Therefore, the student curation was suspended. As a mitigation plan, we are working to move the curation process to be completed online.

Both computing resources utilizations and personnel priority have been affected by prioritized COVID-19 related work. This has caused delays in processing video recordings, data management as well software and website development since March.

3.2 Achievements
We have published two papers during the past year:

The paper presented at ITS World Congress was recognized as the best technical paper from North America.
4. Findings, summary, and discussion

Our work has been focused on the following two major goals: 1) evaluation of pedestrian activities before and after a pedestrian hybrid beacon device installation; and 2) assessment of pedestrian activities at new locations. For the first goal, we have explored additional algorithms for pedestrian tracking code, namely SORT, and refined our pedestrian detection by further limiting regions of interest. We have evaluated the SORT algorithm at Anderson Lane and Burnet Road. For the second goal, we have evaluated two additional locations, Lamar Boulevard and Rundberg Lane and Lamar Boulevard and Payton Gin Road. The use case presented in this work illustrates the potential of implementing deep-learning methods to the study of pedestrian street-crossing patterns. We also propose several metrics of pedestrian activity to support the systematic analysis of before/after scenarios and the quantification of the benefits of pedestrian safety treatments. While preliminary, our results suggest that meaningful metrics may be automatically derived from data recorded by traffic monitoring cameras, which would enable agencies to conduct more thorough analyses on a larger number of locations.

Artificial intelligence technologies can greatly reduce the effort involved in analyzing video data, and frameworks such as the one presented here can facilitate research traditionally based on manual video data analysis and promote further work on video data applications and integration. A unique advantage of our framework is to convert video recordings into query-able information, which can accommodate multiple subsequent use cases without re-processing [3]. While the framework and specific applications are still under development, we have demonstrated their potential to support useful analyses with minimal effort when compared to manual processing.
